

The Period Doubling Operator

Jim Swift at NAU

The doubling operator \mathcal{T} maps a function f to a new function $\mathcal{T}f$, which can also be denoted $\mathcal{T}(f)$. In my slightly unorthodox definition, the domain \mathcal{D} of \mathcal{T} is the infinite-dimensional space of continuous functions $f : [-1, 1] \rightarrow [-1, 1]$ such that

- $f(-1) = f(1) = -1$.
- f has a unique critical point c , and $f''(c) < 0$.
- f has exactly 2 fixed points, -1 and $x^* > c$.

Note that $f \in \mathcal{D}$ is increasing on $[-1, c]$ and decreasing on $[c, 1]$, and $f(c) > c$. There is a unique $x_\ell < c$ such that $f(x_\ell) = x^*$. Define the function $h : [x_\ell, x^*] \rightarrow [-1, 1]$ as the unique linear function that satisfies $h(x^*) = -1$ and $f(x_\ell) = 1$. One formula is $h(x) = -1 + 2\frac{x-x^*}{x_\ell-x^*}$.

The doubled function $\mathcal{T}f : [-1, 1] \rightarrow \mathbb{R}$ is defined by $\mathcal{T}f = h \circ f^2 \circ h^{-1}$.

An important special case is when f is even. In this case $c = 0$ and $x_\ell = -x^*$, so $h(x) = -\frac{x}{x^*}$ and $h^{-1}(x) = -xx^*$. Therefore, $\mathcal{T}f(x) = -\frac{1}{x^*}f^2(xx^*)$. It is traditional in this case to define $\alpha = 1/x^*$, so

$$\text{if } f \in \mathcal{D} \text{ is even, and } f(1/\alpha) = 1/\alpha > 0, \text{ then } \mathcal{T}f(x) = -\alpha f^2(x/\alpha).$$

The Feigenbaum conjectures, proved by Oscar Lanford, are

- \mathcal{T} has a unique fixed point in \mathcal{D} , which is even, denoted by g .
- The linearization of \mathcal{T} at g , $D\mathcal{T}(g)$, has exactly one eigenvalue outside the unit circle. This eigenvalue is $\delta \approx 4.669$. Furthermore, there are no eigenvalues on the unit circle.

This explains why the *Feigenbaum constant* $\delta \approx 4.669$ is a “universal number”. There is another universal number $\alpha \approx 2.503$ defined as the reciprocal of the unique fixed point of g in $[0, 1]$. The “universal function” g satisfies $g(x) = -\alpha g^2(x/\alpha)$.

It should be mentioned that another paper independently discovered this universality: Coulet, P; Tresser, C (1978), “Iteration d’endomorphismes et groupe de renormalisation”, J. Phys. Colloque, 539: 525. Predrag Cvitanović also deserves mention.

Application to the logistic map family $f_a(x) = -1 + \frac{a}{2}(1 - x^2)$, with $0 \leq a \leq 4$: The logistic map f_a is in the domain of \mathcal{T} iff $2 < a \leq 4$.

The doubled map $\mathcal{T}f_a$ is itself in the domain of \mathcal{T} iff $a_2 < a \leq M$, where $a_2 = 1 + \sqrt{5}$, so that f_{a_2} has a superstable period 2 orbit, and $M \approx 3.67857$ is the first Misiurewicz point, where f_M has the 2 to 1 band merging.

The only map in the family f_a such that $\mathcal{T}^n f_a \in \mathcal{D}$ for all n is the one with $a = a_\infty$, at the accumulation of period doublings. Furthermore,

$$\lim_{n \rightarrow \infty} \mathcal{T}^n f_{a_\infty} = g,$$

the universal function.
